HIGHLIGHTS

- Corrosion behavior of steel submitted to chloride and/or sulphate is investigated.
- Chloride threshold value and corrosion threshold value of sulphate are obtained.
- The concomitant presence of chloride and sulphate leads to higher corrosion rate.

ABSTRACT

Electrochemical measurements of open circuit potential, linear polarization and electrochemical impedance spectroscopy (EIS) were utilized to investigate the corrosion behavior and chloride threshold value (CTV) of reinforcing steels submitted to chloride and sulphate attack in simulated concrete pore solution in this study. Determination of corrosion initiation was made by combining half-cell potential ($E_{corr}$) with corrosion current density ($I_{corr}$) as well as EIS curves. Results showed that electrochemical measurements were effective in detecting corrosion behavior of steels. CTV of steels was 0.5–0.6 mol/L in simulated concrete pore solution contaminated by chloride ions while threshold value of steels submitted to sulphate ions was 0.2–0.3 mol/L. The concomitant presence of chloride and sulphate ions led to higher corrosion current density which indicated sulphate ions accelerated the corrosion of reinforcing steels in simulated concrete pore solution.

1. Introduction

Steel reinforcement embedded in concrete normally maintains passive due to the thin iron oxides film which is attributed to the high alkaline environment of concrete. However, once the chloride content at the steel surface reaches a certain level, i.e. chloride threshold value (CTV), when oxygen and moisture in presence, active corrosion of steel is initiated [1–3]. Thus the CTV is defined as the chloride concentration at the depth of steel which triggers active or pitting corrosion. Premature deterioration of reinforced concrete structures induced by steel corrosion has become a serious durability problem throughout the world, leading to significant economic loss [4,5]. Numerous investigations [6–11] have been performed on ingress of aggressive ions and CTV, but reported values are rather scattered. For example, the chloride threshold value presented by total chloride in concrete ranged from 0.04 to 8.34% by weight of binder and from 0.07% to 1.16% expressed by free chloride [12]. Besides, many reinforced concrete structures are exposed to harsh environment where concentrated chloride and sulphate ions coexist like in salt lake district or salinized soil district in northwest China [13]. Previously, a lot of emphasis has been placed on sulphate attack to concrete matrix [13–15] but few reports regarding influence of sulphate ions on steel corrosion are found.

Experiments performed in cement paste, mortar and concrete to investigate CTV of steels are time consuming and are greatly affected by many influencing factors such as cement type, concrete mix proportions, moisture content, temperature and blended materials [12,16], though it may reveal more pertinent results. Therefore many authors have performed studies on steel corrosion in simulated concrete pore solution, a saturated Ca(OH)$_2$ solution in most cases [17,18]. Simulated concrete pore solutions not only reproduce chemical environment in concrete but also shorten the experiment period and provide significant results for cement-based materials.

In the present work, the corrosion behavior of steels submitted to chloride and/or sulphate ions in saturated Ca(OH)$_2$ solution...
(pH = 12.5) was investigated by employing open circuit potential (OCP), linear polarization (LP) and electrochemical impedance spectroscopy (EIS) methods. Corrosion initiation and the CTV were determined by combining half-cell potential (Ecorr) with corrosion current density (Icorr) as well as EIS curves.

2. Experimental program

2.1. Specimen preparation and exposure conditions

Cylindrical steel specimens with a diameter of 16 mm and length of 10 mm were cut from HRB335 steel. The chemical composition of steel samples (by weight) was 0.20% C, 0.55% Si, 1.42% Mn, 0.028% S, 0.026% P and the balance of Fe. One cross-section surface was polished with grit paper to grade 1000 as exposure surface, which is usually assumed to be from 26 mV to 52 mV [20]. The value of B was 2. In this work, the Rp was obtained directly by built-in fitting software. EIS results, where Rs is the solution resistance and Rct the charge transfer resistance, means that the pitting rate value could be higher than 1 μA/cm², which indicates significant active corrosion. Also the CTV could be assumed to be from 0.05 to 0.06 mol/L according to Icorr evolution.

An abrupt change in the Nyquist plots of EIS can also be observed in Fig. 3. A typical Nyquist plot of steel immersed in simulated solution depicts a capacitive loop of depressed semicircles. As the concentration of chloride increases, the radius of the low-frequency semicircle gradually reduces, becoming from “linear” to “semicircular”.

An equivalent circuit shown in Fig. 4 was used to interpret EIS results, where Rs is the solution resistance and Rct the charge transfer resistance.

3. Results and discussion

3.1. Corrosion behavior in chloride contaminated condition

Three parallel steel samples labeled as #1, #2 and #3 are exposed to chloride added stepwise by 0.01 mol/L each day. The evolutions of Ecorr are presented in Fig. 1. It can be found that the average Ecorr of specimens after ten days of pre-passivation is around −230 mV vs. SCE. With the additions of chloride, The Ecorr decreases gradually and moves to negative values, which means a higher risk of corrosion. Then the Ecorr drops dramatically when a certain content of chloride is added, indicating the breakdown of passive film and initiation of active corrosion. The CTV of steels can be inferred to be from 0.05 to 0.06 mol/L.

The evolutions of Icorr obtained from the LP and Eq. (1) are depicted in Fig. 2. With lower concentration of chloride, Icorr keeps a steady low value. When chloride content exceeds a certain level, Icorr denotes a sudden shift to greater values, indicating high corrosion rate. It should be noted that the pit growing rate (penetration depth rate) is assumed to be around 10 times higher than the average corrosion rate measured [21]. An Icorr of 0.1 μA/cm² means that the pitting rate value could be higher than 1 μA/cm², which indicates significant active corrosion. Also the CTV could be assumed to be from 0.05 to 0.06 mol/L according to Icorr evolution.
transfer resistance. A greater $R_{ct}$ value means more difficult for corrosion.

Constant phase element (CPE) represents the double-layer capacitance of the steel/electrolyte interface, and its impedance $Z_{CPE}$ is defined as in Eq. (2).

\[
Z_{CPE} = \frac{1}{Y_0 j\omega^n}
\]

where $Y_0$ is a parameter proportional to the double layer capacitance of pure capacitive electrodes, $\omega$ is the frequency in radians per second and $n$ represents the deviated degree of the capacitance from the ideal condition, which ranges from 0 to 1. The CPE becomes a resistor when $n = 0$ and a capacitor when $n = 1$. In the concrete/steel system, passive film capacitance and double layer capacitance usually deviate from pure capacitance due to the dispersion effect, and the CPE is used instead of pure capacitance to represent the non-ideal frequency dependent capacitance in equivalent circuits. The behavior of CPE can be the result of the fractal nature or heterogeneity of electrode interface.

The fitting results of EIS data using the equivalent circuit are listed in Table 1. $R_s$ value reduces steadily with additions of chloride, which means lower resistivity with more ions in electrolyte. $R_{ct}$ reduces gradually as chloride content is increased. When the chloride content reached the CTV, between 0.05 and 0.06 mol/L in this case, $R_{ct}$ declined rapidly by orders of magnitude due to the breakdown of passive film of steels. It can be seen that the CTVs concluded from $E_{corr}$, $I_{corr}$ and EIS are in good consistency.

Additionally, when the steel electrode is immersed in simulated pore solution, a double electric layer or passive film tends to be established, making the solution/steel interface act more as pure capacitance and therefore the value of $n$ is close to 1. Under chloride attack, passive film gradually breaks down, resulting in higher value of $Y_0$ and lower value of $n$.

3.2. Corrosion behavior in sulphate ions contaminated condition

Steel specimens labeled as #4, #5 and #6 exposed to sulphate ions attack show similar trend in $E_{corr}$ compared to those in chloride contaminated conditions as can be seen in Fig. 5. With increasing sulphate ions, the $E_{corr}$ levels off until a certain content of sulphate is added and a sharp decline in $E_{corr}$ occurs. Compara-

To chloride threshold value, a sulphate threshold value of 0.02 mol/L can be inferred from this work. It is believed that the modification of the original iron oxide film to ferric sulphate film which was less protective caused the corrosion of steels subjected to sulphate ions [22,23]. It has been identified that sulphate shows a lower threshold value compared to chloride.

Likewise, a sudden shift in $I_{corr}$ is shown in Fig. 6 when content of sulphate ions comes to threshold value. In the early stage, corrosion rate maintains low speed. When it exceeds the sulphate threshold content, pitting corrosion develops fast, leading to higher $I_{corr}$. It is notable that the initial $I_{corr}$ of #4 sample are relatively higher than other samples probably due to inhomogeneity in local areas on the steel surface.

Typical Nyquist plots of specimen with increasing additions of sulphate ions are shown in Fig. 7. The capacitive loop in low frequency presents an obvious compressing trend between 0.02 and 0.03 mol/L of sulphate ions. Fitting data of EIS using equivalent circuit are listed in Table 2. The $R_{ct}$ decreases by one order of magnitude when sulphate content changes from 0.02 to 0.03 mol/L.

3.3. Corrosion behavior in composite chloride-sulphate contaminated condition

In this part, pre-passivated steel specimens are exposed to chloride contaminated condition containing 0.6 mol/L of NaCl (3.5% by weight) and sulphate ions.
weight) to simulate marine service environment. Then sample #7, #8 and #9 were added with fixed concentration of chloride and 0.01 mol/L sulphate ions and were tested after 1d while sample #10, #11 and #12 are exposed to fixed concentration of chloride only.

Fig. 8 depicts the evolution of Ecorr of all specimens. It can be seen that Ecorr of all samples has gone below \(-500 \text{ mV}\) after 24 h of exposure to 3.5% of NaCl. With or without further sulphate additions, Ecorr of all samples remain steady between \(-500\) and \(-600 \text{ mV}\). However, samples with sulphate attack show marked difference in Icorr as is shown in Fig. 9. Sulphate ions added stepwise results in even higher Icorr than that without sulphate addition. High corrosion current density indicates fast pitting or general corrosion speed. From the results of this study, the concomitant presence of chloride and sulphate ions led to higher corrosion current density, which indicated severer corrosion of steel in simulated concrete pore solution. However, the precise mechanism through which sulphate ions influence the reinforcement corrosion is not well understood. It is inferred that a porous and non-passivating corrosion product layer formed by sulphate ions allows corrosion process to continue undisturbed. However, other researchers [24] attributed the comparative increase in corrosion rates to higher conductivity stemming from concentrated sulphate.

Typical Nyquist plots of specimen subjected to fixed concentration of chloride and varying concentrations of sulphate are shown in Fig. 10. The low-frequency arc reveals a dramatic change when chloride and sulphate are added. With subsequent dosage of sulphate ions, the compressing trend of capacitive semicircle continues. An obvious change of fitted Rct can be found in Table 3. The Rct decreased from \(8.336 \times 10^5\) to \(1.157 \times 10^4\) when fixed concentration of chloride and 0.01 mol/L sulphate ions are added and keeps reducing with more sulphate ions added.

4. Conclusion

Corrosion behavior and chloride threshold value of steels subjected to chloride and/or sulphate ions have been investigated in simulated concrete pore solution in this work. Electrochemical measurements of OCP, LP and EIS are utilized in combination to monitor corrosion evolution. Physical experiments were carried out not only to provide useful guidance and reference for specialists and engineers, but also to cast light upon likely corrosion mechanism when both chloride and sulphate are present. The following conclusions have been obtained:

1. A good correlation between OCP, LP and the EIS measurement has been found in monitoring corrosion behavior of steels. Determination of corrosion onset is suggested to use these non-destructive methods in combination. Eccor, Icorr and Rct value have shown dramatic shift when aggressive ions reaches the threshold value.

2. The CTV of steels submitted to chloride ions obtained in this work is between 0.05 and 0.06 mol/L, whereas the corrosion threshold content of sulphate ions ranges from 0.02 to 0.03 mol/L. Lower threshold content means sulphate presents more aggressive corrosion risk to steel, partially due to the porous and non-passivating corrosion product induced by sulphate.

3. The concomitant presence of chloride and sulphate ions leads to higher corrosion current density than specimens exposed to chloride ions at corresponding concentration, which indicated corrosion rate of steel specimens accelerates when both chloride and sulphate are in presence in simulated concrete pore solution.
